Abstract

**Purpose:** We aimed to investigate the potential early diagnostic value of Ischemia Modified Albumin (IMA) and D-dimer in testicular torsion.

**Material and Methods:** A total of 42 prepubertal Wistar-Hannover rats (26-30 days old, weighing 75-125 grams) were used in the study. They randomly divided into 2 groups as torsion (21 rats) and control (21 rats). Both torsion and control groups were subdivided into three subgroups as 30th, 120th and 240th minutes. Intraperitoneal injection of 70 mg/kg ketamine (Ketalar, Pfizer, Istanbul, Turkey) plus 10 mg/kg of xylazine (Rompun, Bayer, Istanbul, Turkey) were used for general anesthesia. In the control group, scrotal incision was made and the left testis gently extracted. Then, intracardiac blood and testicular tissue were obtained at 30th, 120th and 240th minutes. In torsion group, testicular ischemia was achieved by rotating left testis 720° clockwise and maintained by fixing the testis. Blood and testicular samples were obtained at 30th, 120th and 240th minutes. All animals were sacrificed after completion of the study.

**Results:** There was a statistically significant difference between the IMA and D-dimer levels at 30th, 120th and 240th minutes of torsion group when compared with the control group (p=0.001). When compared in terms of pathological changes at 30th, 120th and 240th minutes, significant difference was found for all 3 periods (p=0.039, p=0.014, p=0.03, respectively). The D-dimer and IMA estimated torsion with reasonable accuracy [Area under the curve (AUC)= 0.771 (0.620-0.922, p= 0.003, 95% confidential interval) and AUC=0.706 (0.549-0.863, p=0.022, 95% confidential interval), respectively].

**Conclusion:** The elevated serum D-dimer and IMA levels observed in the experimental testicular torsion model seem to have a potential role as a serum marker in the early diagnosis of testicular torsion.
Introduction

Testicular torsion (TT) occurs due to the loss of blood flow to the testis and surrounding tissues as a result of spermatic cord rotation.\textsuperscript{1} Testicular recovery is likely if intervention is performed within the first 6 hours after the onset of symptoms.\textsuperscript{2-4} Testicular torsion causes ischemic injury; detorsion causes reperfusion damage and they both cause structural and biochemical changes in the testis.\textsuperscript{5-7} In case of ischemia, cellular stress factors such as hypoxia, acidosis, free radical damage and deterioration of membrane integrity changes the structure of the albumin molecule. At the N-terminal end of the albumin, some changes that reduce the binding capacity of transitional metals such as copper, cobalt and nickel occur. This newly formed damaged albumin is called as ‘Ischemia Modified Albumin’ (IMA).\textsuperscript{8-10} D-dimer is a degradation product of fibrin. Local fibrin formation and lysis are part of the inflammatory response and fibrin degradation products such as D-dimer, regulate the acute phase response and the production of systemic inflammatory mediators. Both markers are mainly elevated in ischemic-hypoxic and thromboembolic conditions\textsuperscript{11-16}.

Examination of testicular blood flow by color doppler ultrasonography (USG) or scintigraphy are the main diagnostic methods in the diagnosis of TT. However, these methods may not be easily accessible in every case. So, there is a need for fast laboratory tests which are practical, easily accessible and which have a high diagnostic value. Some limited animal studies have shown that IMA and D-dimer can have a significant value in the diagnosis of TT.

In this experimental study, we aimed to investigate the role of serum levels of IMA and D-dimer in the early diagnosis of TT in prepubertal rats. Since TT is mostly seen in pediatric age group and young adults, we preferred to use prepubertal rats.
Material and methods

Study design and animals

The present animal study was approved by Bezmialem Vakif University (BVU) Local Ethics Committee of the Animal Experiments (IRB number: 2018/18) and was carried out in the BVU Experimental Animal Research Laboratory. Animals used in the experiment were kept in steel cages at a room temperature of 22°C and were fed with normal water and standard food until the day of the study. Water only diet was provided for the last 12 hours before the induction of the study. A total of 42 experimentally naïve and drug-naïve male prepubertal Wistar-Hannover rats were used in the study. They randomly divided into 2 groups as torsion (21 rats) and control (21 rats). Both torsion and control groups were subdivided into three groups as 30th, 120th and 240th minutes. Intraperitoneal injection of 70 mg/kg ketamine (Ketalar, Pfizer, Istanbul, Turkey) plus 10 mg/kg of xylazine (Rompun, Bayer, Istanbul, Turkey) were used for general anesthesia. In control group, scrotal incision was made and the left testis gently extracted. Then intracardiac blood and testicular tissue were obtained at 30th, 120th and 240th minutes. In torsion group, testicular ischemia was achieved by rotating left testis 720° clockwise and maintained by fixing the testis. Blood and testicular samples were obtained at 30th, 120th and 240th minutes. All animals were sacrificed after completion of the study.

Biochemical investigations

To measure serum IMA and d-dimer levels, Rat IMA ELISA kit (Catalog No. CK-E91024, Eastbiopharm., Hangzhou Eastbiopharm Co. Ltd.) and Rat d-dimer (D2D) ELISA kit (Catalog No. CK-E91432, Eastbiopharm., Hangzhou Eastbiopharm Co. Ltd.) were used, respectively. Specimen absorbances were determined on a Biotek ELX800 (Biotek, Winooski, VT, USA) microplate reader at a wavelength of 450 nm. The IMA results were expressed in IU/mL and
the minimum detectable level was 1 IU/L. The d-dimer results were expressed in ng/mL and the minimum detectable level was 5 ng/L.

**Histopathological examinations**

Testicular tissues were fixed in 10% formaldehyde solution and they were embedded into paraffin for follow-up procedures. Standard sections of four microns were prepared and they stained with hematoxylin and eosin (H&E). The slides were evaluated by using a light microscope and classified according to the classification system which was designed by Cosentino et al.\(^\text{17}\);

*Stage 1:* Normal testicular tissue (Figure-1A)

*Stage 2:* Less regular germ cells, irregular convergent seminiferous tubules (Figure-1B)

*Stage 3:* Irregular germ cells, diminished pycnotic nuclei and destructed bounded seminiferous tubules (Figure-1C)

*Stage 4:* Seminiferous tubules filled with irregular germ cells which have coagulation necrosis (Figure-1D)

**Statistical analysis**

Data were analyzed by using Statistical Package for the Social Sciences software package version 16 (SPSS Inc., Chicago, IL, USA). Descriptive analyses were presented using median, interquartil range (IQR), minimum and maximum for non-normally distributed variables. The Wilcoxon test was used to compare torsion group with it’s control group. More than two group comparisons were made by Kruskal Wallis test; if there was a significant difference Mann Whitney U test was performed to test the significance of pairwise differences using Bonferroni correction (p=0.05/30=0.017) to adjust for multiple comparisons. The comparison of torsion group with its control group in terms of pathological staging was performed with the chi-square
test. Cut-point value was determined by ROC Curve Analysis. Statistical significance was accepted as p <0.05.

**Results**

The characteristic of the rats were shown in Table-1. Serum IMA and D-dimer levels of torsion and control groups were summarized in Table-2. There was a statistically significant difference between the IMA and d-dimer levels at 30th, 120th and 240th minutes of torsion group when compared with the control group (p=0.001). There was a significant difference in terms of IMA levels between subgroups of the torsion group. (30th vs 240th minutes and 120th vs 240th minutes, p=0.002 and p=0.006, respectively). However, no significant difference was detected in terms of D-dimer values (p=0.174).

When torsion and control groups were compared in terms of pathological changes at 30th, 120th and 240th minutes according to the Cosentino et al classification, significant difference was found for all 3 periods (p=0.039, p=0.014, p=0.03, respectively). In the torsion group, the mean Cosentino stage was 2.6, 3.3 and 3.4 at 30th, 120th and 240th minutes, respectively. However, these values were between 1.1 and 2.1 in the control group.

The receiver operating characteristics (ROC) curves of both markers are shown in Figure-2. The D-dimer and IMA estimated torsion with reasonable accuracy [Area under the curve (AUC)= 0.771 (0.620-0.922, p=0.003, 95% confidential interval) and AUC=0.706 (0.549-0.863, p=0.022, 95% confidential interval), respectively].

Sensitivity, specificity and predictive values of D-dimer and IMA are shown in detail in Table-3 and Table-4. At a cut-off point of 118.9 mg/dL, the D-dimer has a sensitivity of 90.5%, specificity of 61.9%, PPV of 70.4% and NPV of 86.7%. The IMA was 81% sensitive and 52.4% specific in the diagnosis of TT at a cut-off point of 35.5 mg/dL.
Discussion

Viability and preservation of testis in TT is dependent on the degree and the duration of TT. It has been shown that 360 degrees of TT does not have an effect on fertility, whereas, 720 degrees and above of TT have negative impacts on fertility. It has been stated that chances of testicular preservation in 6, 12 and 24 hours of TT is 90%, 50% and 10%, respectively.\(^6\) Therefore, immediate diagnosis and treatment of TT is required in order to preserve testis and fertility.

Sensitive and specific laboratory parameters which may aid in the early diagnosis of TT are limited. Suspicion of TT generally ends up with surgical exploration of the testis. A sensitive, fast and practical biochemical markers are of importance as it would serve as adjunct to diagnosis and increase efficiency of TT management. The D-dimer and IMA assays are fast and practical laboratory tests that are routinely available in an outpatient setting via quantitative assays. Therefore, in the present animal model, we studied the D-dimer and IMA markers. Both markers are mainly elevated in ischemic-hypoxic and thromboembolic conditions. Because of fact that torsion is an ischemic condition and it creates thrombotic formations in arterial and venous vasculature, it is expected that the D-dimer and IMA levels increase in ovarian and testicular torsion.

IMA measurement has recently been proposed as a sensitive marker for the diagnosis of myocardial ischaemia. Clinical usage of IMA in pathological conditions have grown in number, with the additional using in deep venous thrombosis, pulmonary thromboembolism, lower limb ischaemia, cerebrovascular events and disseminated intravascular coagulation. Also, IMA is regarded as a marker of oxidative stress related to ischaemia reperfusion in any organ, because it is found elevated in various clinical entities associated with oxidative stress such as systemic sclerosis, type-2 diabetes and polycystic ovary syndrome.\(^{17}\)
In an animal torsion model study by Mentese et al., detorsion was performed 4 hours later and testicular tissues were histopathologically examined 2 hours and 2 weeks after. IMA values were found to be elevated in early and late stages. The authors stated that IMA values were valuable in evaluation of acute and long-term testicular injury and evaluation of fertility capacity.\textsuperscript{11} In contrary to our study, the samples were obtained after TT, thus, the effect of reperfusion on histopathological results were inevitable. In our study, we have investigated markers which can aid in early diagnosis of TT, ischemia was performed but detorsion was not applied and effects of reperfusion was not investigated. In an experimental ovarian ischemia/reperfusion (I/R) model, IMA values were found to be higher when compared with the control group and also, positive correlation between IMA values and histopathologic results were detected in I/R group.\textsuperscript{12}

In an experimental testicular torsion, it was shown that an increase of D-dimer level could be detected in the blood of rats within 4 hours.\textsuperscript{13} Other experimental studies showed that D-dimer started to increase in minutes after the onset of ischemia and reached its’ highest value in 6-12 hours.\textsuperscript{14-15} All these results suggest that D-dimer can be a potential valuable marker in the early diagnosis of TT. In the present study, the predictive characteristics of the both markers (D-dimer and IMA) were satisfactory (AUC=0.771 and AUC=0.706, respectively; these results can be interpreted as reasonable accuracy). In the patients who had ovarian torsion, D-dimer sensitivity was detected to be 71.4% and specificity was detected to be 85% in ROC curve analysis.\textsuperscript{14}

Other than IMA and D-Dimer, some new biomarkers have been proposed in early diagnosis of TT. In a randomized, controlled, experimental study, Turedi et al studied plasma SCUBE1 (a novel marker of platelet activation) protein and they proposed that its’ measurement may have adiagnostic, therapeutic or prognostic value in TT.\textsuperscript{7} In a clinical study, Gunes et al investigated some hematological parameters (neutrophil / lymphocyte ratio; NLR,
platelet/lymphocyte ratio (PLR), mean platelet volume (MPV), and platelet) and they claimed that NLR may be used as a predictive factor for testicular viability following TT. Peretti M et al proposed that the lower MPV value in "early-presenting" patients with TT suggests a role in predicting the testis viability. Gul et al reported that caspase-3 immunoreactivity increased in the torsion group and that melatonin and melatonin plus pulsed magnetic field (PMF) treatment reduced the rate of immunoreactivity. Despite these promising results, there is a need for further studies to routinely use these markers in clinical practice.

Conducted studies have generally focused on the ischemia/reperfusion injury and approaches to treatment. Postpubertal rats were used in almost all of them. We investigated the ischemia markers on pre-pubertal rats. However, our study has some limitations. The major limitation is the relatively small sample size; thus, large-scale randomized experimental and clinical trials are encouraged to be designed, so that the above conclusions can be verified with an increased statistical power. Other biochemical markers were not studied in our study and this can be cited as another limitation.

**Conclusions**

On the basis of the findings from this experimental study, serum D-dimer and IMA levels are significantly higher in rats with TT compared to control group. The elevated serum D-dimer and IMA levels seem to have a potential role as a serum marker in the early diagnosis of TT. Future investigations about biomarkers in the early diagnosis of TT should be the focus of further clinical studies.
Acknowledgement

For the expenses (IMA ELISA kit and D-Dimer ELISA kit) in the present study, financial support was provided from the Academic Studies Committee of Haseki Training and Research Hospital. We are thankful to the Academic Studies Committee of Haseki Training and Research Hospital.
